Teijin Twaron

Abstract

Teijin Twaron is a company that develops and produces fibres for bullet proof vests. In order to compare two fibres (or two bullet proof vests made of two different fibres for that matter) they want to determine the velocity $V_p$ at which $p$ percent of the bullets pass through the vest, in particular when $p = 50\%$. The objective of this research is to find good estimates for $V_p$. The available data have been analysed to examine which aspects influence the probability of perforation and have to be taken into consideration to determine $V_p$. Next, a general framework has been developed in which the notation is introduced. Several approaches are proposed to find good estimates for $V_p$. All methods are numerically illustrated. We recommend Teijin Twaron to use loss functions. But a logistic model or an isotonic regression approach with linear interpolation performs also well. The paper ends with a new procedure how the data should be gathered to determine $V_p$.

**Keywords:** quantile estimation, classification tree, generalised linear models, isotonic regression, smoothing splines, bootstrap method

1 Introduction

Having a good bullet proof vest to protect your body is important if you are in a gun fire or battle field. A few years ago a bullet proof vest contained metal and was

*corresponding author
therefore rather heavy to wear. The current vests are made of multiple layers of fibre, which make the vests much lighter. Teijin Twaron B.V. is a producer of these fibres. When they develop a new kind of fibre they make bullet proof vests out of it and test the quality of the vest. The easiest way to compare the quality of two vests is to determine for both vests the velocity at which fifty percent of the bullets pass through. This velocity will be denoted by $V_{50}$. A higher $V_{50}$ means a better quality vest. The determination of the $V_{50}$ is rather easy, since the event for a bullet to perforate the vest is equal to non-perforating the vest at this velocity. When this is simulated the number of times either event happens is the same on the long run.

The procedure Teijin Twarom uses to gather the data in determining $V_{50}$ is to shoot at a particular vest 6 times with the same speed of the bullet and repeat this for 7 vests made from the same fibre but for different velocities. The first velocity they shoot with, is based on the estimate where they think $V_{50}$ is at. When more than 3 of the 6 shots perforate the vest, the next velocity they shoot with is decreased with 50 m/s. Otherwise, it will be increased with 50 m/s. This procedure is repeated 7 times. So, it is some kind of evolution towards $V_{50}$.

Based on these 42 data records Teijin Twaron estimates $V_{50}$. First they group the data records in intervals based upon the velocity, with an interval length of 5 m/s. They average out the observations of perforating the vest within each interval. Next, a cumulative density function of the normal distribution is fitted into the new data points. How to fit such a function is explained in more detail in Section 4. Based upon the inverse of this function they determine $V_{50}$. Teijin Twaron wants to use the same function to determine the velocity at which an arbitrary percentage $p$ of the bullets perforates the vest, in particular for $p$ equal to 1%. This velocity is denoted by $V_{01}$ and for a general $p$ by $V_p$.

In toxicology we find studies that are similar to this research. A general introduction can be found in Agresti [1], Agresti [2] and Emmens [8]. In these toxicology studies, the interest lies in determining models to describe the relationship between the probability of reacting to a certain toxic chemical as a function of the given dose of this chemical. More specifically, for different dose levels, the researchers observe whether the dose results in a toxic reaction.

In this paper we will improve the procedure to determine $V_p$ once the data is provided. But we will also design a new test procedure to gather the data that is used to determine $V_p$. In Section 2 we start with an analysis of the data Teijin Twaron currently uses. A general framework is presented in Section 3, in which we also introduce notation and a general set-up to compare different techniques. In Section 4 until Section 6 we present different techniques to derive a function that maps a velocity on the probability of perforating a particular vest. In Section 4 we will use Generalised Linear Models (GLMs), while the techniques discussed in Section 5 do not impose a predefined functional form. The last technique to estimate $V_p$ is a bootstrap method. This approach determines $V_p$ based upon a characteristic at this velocity instead of finding the inverse of a function. In Section 7 we propose a new procedure to gather the data. In Section 8 we compare the different solution techniques and give a conclusion which method we recommend.
2 Data analysis

The data set provided by Teijin Twaron contains the 42 data records as explained in Section 1 for 9 different vest types. Each data record consists of whether the bullet perforated the vest (this is also called the perforation status), the velocity of the bullet which was shot at the vest, the shot number (1 to 6), the vest number (1 to 7) and the vest type. For one particular vest type the data set contains 126 data records.

The objective of the statistical analysis of the data is to provide an overview of the relationships between the perforation probability (also called the response variable) and its four explanatory variables or covariates, i.e. the bullet velocity, the shot number, the vest number and the vest type. The model employed in this analysis explains the observed variability of the data without making any assumption on the physical or chemical mechanisms which might have played a role in generating the samples. This means that all data records for the different vest types under investigation are used all together in this analysis.

In the analysis the entire sample is modeled according to a classification tree (Breiman et al. [4]). This is a semiparametric statistical model in which the data is partitioned among several subsamples with significantly different perforation probabilities. The data subgroups are defined by a binary tree where the splits are functions of the covariates. For instance, two groups can be obtained by considering the samples with a bullet velocity smaller than 400 m/s and those with a velocity larger than or equal to 400 m/s. Within the latter group, two clusters of data points can be formed by dividing the samples associated to a particular vest type versus those corresponding to all other vest types, and so on. We will refer to the groups of data generated by a given tree structure as its leaves. In this analysis we do not assume any specific distribution on the space of tree structures, whereas within each leaf we model the perforation status as a Bernoulli random variable with a leaf-specific perforation probability.

In order to estimate the tree structure we perform a stochastic search using the probability of the tree given the data as the score function. This is a simulation-based computationally intensive method which evaluates the uncertainty on the specification of the tree structure conditionally on the sample (Breiman et al. [4], Chipman et al. [5], Chipman et al. [6], Denison et al. [7], Holmes et al. [13]). Given the best tree structure found by the stochastic search, we estimate the leaf-specific perforation probabilities in a Bayesian fashion. In particular, for each leaf we assume a uniform prior perforation probability. By combining this prior with the Bernoulli likelihood we obtain a Beta perforation probability given the samples falling in the leaf. The Beta distribution can be summarised analytically, providing both a point estimate of the leaf-specific perforation probabilities and their confidence intervals.

Figure 1 shows the results of the estimation of the tree structure when all data is analysed. The tree has a total of eight leaves, which cluster the samples as a function of the bullet velocity and shot number. Notice that this tree structure does not depend on the vest type. This surprising result is emphasised in Table 1. For each of the four available covariates, the table shows its estimated probability of inclusion in the tree structure. The covariates with the highest predictive power
are the bullet velocity and the shot number but the vest type does not appear to discriminate groups of samples with significantly different perforation probabilities.

Figure 1: The tree structure which fits the data the best.

Table 1: The estimated inclusion probabilities for the four covariates to incorporate them into the classification tree.

Finally, the estimated perforation probabilities for the eight leaves of the tree are presented in Table 2. It can be noted that the estimated perforation probability appears to be increasing in the bullet velocity. Moreover, at any given bullet speed, the estimated perforation probability of the first shot is lower than of the second shot, which in turn is higher than any of the other shot numbers.

Table 2: The estimated perforation probabilities including the 95% confidence intervals for the eight leaves of the tree.

Although Figure 1 and Table 1 make clear that only the velocity and shot number are of relevance to determine the probability of perforation, we consider the velocity and vest type as explanatory covariates in this research. The main reason to take the vest type into consideration is because Teijin Twaron wants to compare different vest types. The shot number is not used as covariate, since the shooting pattern should result in independent shots. Apparently this is not the case. Therefore, we advise Teijin Twaron to look at this. But in the remainder of this paper, we will use all data records of one particular vest type to determine $V_{50}$ based upon the speed of the bullet. A motivation not to take the shot number into consideration is to have a bigger sample set. Otherwise there are only 7 data records available.
3 General Framework

A procedure has to be developed to determine \( V_p \); the velocity at which \( p \) percent of the bullets perforates the vest. Since we do not take the shot number or the vest number into account (see Section 2), the data records of one vest type are presented by \((X_i, Y_i)\)-pairs. The velocity of the \( i \)-th shot (expressed in m/s) is denoted by \( X_i \) and the event of a perforation by \( Y_i \), where

\[
Y_i = \begin{cases} 
1, & \text{if shot } i \text{ perforated the vest,} \\
0, & \text{otherwise.} 
\end{cases}
\] (1)

The number of data records is denoted by \( N \), so \( i = 1, \ldots, N \). Whenever the data set is rearranged into intervals with an interval length of 5 m/s, the \((X_i, Y_i)\)-pairs are transformed into \((X'_j, Y'_j)\)-pairs where \( X'_{j+1} = X'_j + 5 \). The new response variable \( Y'_j \) becomes the average probability of perforating the vest where the velocity of the bullet is in interval \( j \):

\[
Y'_j = \left[ \sum_{i=1}^{N} 1_{X_i \in [X'_j - 2\frac{1}{2}, X'_j + 2\frac{1}{2})} \right]^{-1} \sum_{i: X_i \in [X'_j - 2\frac{1}{2}, X'_j + 2\frac{1}{2})} Y_i,
\]

where \( 1_{\text{condition}} \) is the indicator function:

\[
1_{\text{condition}} = \begin{cases} 
1, & \text{if condition is satisfied,} \\
0, & \text{otherwise.} 
\end{cases}
\]

Figure 2 shows the \((X_i, Y_i)\)-pairs as well as the \((X'_j, Y'_j)\)-pairs for the data set where 126 data records are available for a particular vest type.

For every vest type we are interested in finding a function \( f(v) : \mathbb{R}_+ \rightarrow [0, 1] \) that maps a velocity \( v \) onto the probability of perforating the vest when the bullet has speed \( v \). By taking the inverse \( (f^{-1}(p) : [0, 1] \rightarrow \mathbb{R}_+) \) we find \( V_p \). In Section 4 and Section 5 different approaches are proposed to find an appropriate \( f(v) \). A bootstrap method is described in Section 6 to determine \( V_p \) directly.

In order to compare the different techniques we have to define a measure of fitness that relates the differences between the function \( f(v) \) and the data \((X_i, Y_i)\) for \( i = 1, \ldots, N \). A classical measure of discrepancy is the mean squared error (MSE) as defined in Equation (2).

\[
MSE = \frac{1}{N} \sum_{i=1}^{N} [f(x_i) - y_i]^2,
\] (2)

where \((x_i, y_i)\) are the observed realisations of the stochastic variables \( X_i \) and \( Y_i \). Small deviations are not penalised as much as large deviations in this definition for the fitness measure.

4 Generalized Linear Model

Generalized linear models (GLMs) are generalizations of the linear model (see McCullagh, et al. [14]). In its simplest form, a linear model specifies the linear relationship between a dependent (or response) variable, and a set of predictor variables (or
covariates). In this research it is inadequate to describe the observed data (perforation status $Y_i$) with a linear relationship between the variables (bullet speed $X_i$). The main reason for this is that the effect of the velocity on the perforation status is not linear in nature.

### 4.1 Link function

In generalized linear models a so-called link function, denoted by $g$, specifies the connection between the response variable $Y_i$ and the covariate $X_i$. For each experiment, the response $Y_i$ can take only one of two possible values, denoted for convenience by 0 and 1 (see also Equation (1)). Therefore, we may write

$$ P(Y_i = 0) = 1 - \pi_i \quad P(Y_i = 1) = \pi_i $$

for the probabilities of non-perforation and perforation respectively. Linear models play an important role in both applied and theoretical work. We suppose therefore that the dependence of $Y$ on $X$ occurs through the linear predictor $\eta_i$ given by

$$ \eta_i = \beta_0 + \beta_1 X_i, \quad i = 1, \ldots, N $$

Figure 2: The rough data (i.e. the $(X_i, Y_i)$-pairs) and the rearranged data (i.e. the $(X'_j, Y'_j)$-pairs) are represented by block dots and red triangles respectively, for one particular vest type.
for unknown coefficients $\beta_0$ and $\beta_1$. For binary random variables the link function $g$ should map the interval $[0, 1]$ onto the whole real line $(-\infty, \infty)$. So,

$$g(\pi_i) = \eta_i = \beta_0 + \beta_1 X_i, \quad i = 1, \ldots, N.$$ 

A wide choice of link functions is available. Three link functions commonly used in practice are

1. the logit or logistic function

$$g(\pi) = \log \left( \frac{\pi}{1 - \pi} \right),$$

2. the probit or inverse Normal function

$$g(\pi) = \Phi^{-1}(\pi),$$

3. the complementary log-log function

$$g(\pi) = \log \left( -\log(1 - \pi) \right).$$

The first two functions are symmetrical in the sense that

$$g(\pi) = -g(1 - \pi).$$

All three functions are continuous and increasing on $(0, 1)$. This last characteristic is exactly what is required for this research.

To give an example, we look at the logit function

$$g(\pi_i) = \log \left( \frac{\pi_i}{1 - \pi_i} \right) = \beta_0 + \beta_1 x_i$$

$$\pi_i = \frac{\exp(\beta_0 + \beta_1 x_i)}{1 + \exp(\beta_0 + \beta_1 x_i)}.$$ 

This expression equals $f(v)$ based on Equation (3). By inverting this expression we can determine $V_p$:

$$f(V_p) = p = \frac{\exp(\beta_0 + \beta_1 V_p)}{1 + \exp(\beta_0 + \beta_1 V_p)} \quad \Leftrightarrow \quad V_p = \frac{\log \left( \frac{p}{1-p} \right) - \beta_0}{\beta_1}.$$ 

The same can be done for the other link functions. The results are summarised in Table 3.

When we combine the probit model with the rearranged data (see Section ??) we get the current approach to determine $V_p$ (see Section 1).

### 4.2 Alternative Predictor

A disadvantage of all three link functions is that the inverses have support on the entire real axis. This means that a velocity of 0 m/s results in a strictly positive probability of perforating the vest. This phenomena is absolutely not true in the experimental setting. A possible solution is to define an alternative predictor \( \eta_i \) as

\[
\eta_i = \beta_0 + \beta_1 \log(X_i).
\]

For example, the alternative logit function results in

\[
\pi = \frac{\exp(\beta_0 + \beta_1 \log(x_i))}{1 + \exp(\beta_0 + \beta_1 \log(x_i))},
\]

and

\[
V_p = \exp\left(\frac{\log\left(\frac{p}{1-p}\right) - \beta_0}{\beta_1}\right) = \left(\frac{p}{1-p}\right)^{1/\beta_1} \exp(-\beta_0/\beta_1).
\]

Having selected a particular model, it is required to estimate the parameters \( \beta_0 \) and \( \beta_1 \). The parameter estimates are the values that minimize the goodness of fit between the observed data (\( y_i \)) and the fitted values generated by the model (\( \pi_i \)). We are concerned with estimates obtained by maximizing the likelihood of the parameters for the data observed. This principle is explained in the next subsection.

### 4.3 Maximum Likelihood

The likelihood of the data is the probability of observing the data for certain parameter values (Ross [16]) and is expressed by Equation (4).

\[
L(\beta_0, \beta_1; y_1, \ldots, y_N) = \prod_{i=1}^{N} p_{\pi_i}(y_i|\beta_0, \beta_1),
\]

where \( p_{\pi_i}(y_i|\beta_0, \beta_1) \) is the probability of observing \( y_i \) when the probability of perforation equals \( \pi_i \) if \( \beta_0 \) and \( \beta_1 \) are the parameter values. Because of the definition in Equation (3), we should get

\[
p_{\pi_i}(y_i|\beta_0, \beta_1) = \begin{cases} 
\pi_i, & \text{if } y_i = 1, \\
1 - \pi_i, & \text{if } y_i = 0 
\end{cases}
\]

8
and, therefore,
\[ p_{\pi_i}(y_i|\beta_0, \beta_1) = \pi_i^{y_i}(1 - \pi_i)^{1-y_i}. \] (6)

This expression can be substituted into Equation (4) to define the likelihood function. A same kind of expression can be derived when the variable \( Y_j' \) is used in stead of \( Y_i \). Only then, Expression (3) is not valid anymore.

The objective is to find the values of the two estimators, which maximize the likelihood function. Often it is easier to maximize the log-likelihood function because it is easier to manipulate mathematically. Therefore, we derive this by taking the natural logarithm of the likelihood function. When we use Equation (6) in Equation (4) and take the natural logarithm, we get

\[ l(\beta_0, \beta_1; y_1, \ldots, y_N) = \log L(\beta_0, \beta_1; y_1, \ldots, y_N) = \sum_{i=1}^{N} \left[ y_i \log \left( \frac{\pi_i}{1 - \pi_i} \right) + \log(1 - \pi_i) \right] \]

For the logit function, the log-likelihood function equals

\[ l(\beta_0, \beta_1; y_1, \ldots, y_N) = \sum_{i=1}^{N} \left[ y_i (\beta_0 + \beta_1 x_i) - \log \left( 1 + \exp(\beta_0 + \beta_1 x_i) \right) \right]. \]

The log-likelihood function is differentiable in this study. Therefore, the values of \( \beta_0 \) and \( \beta_1 \) that maximize the log-likelihood can be found by solving the first order conditions for the two parameters.

### 4.4 Numerical Results

The classical GLMs (Section 4.1) and alternative GLMs (Section 4.2) are implemented. Figure 3 shows the results when the dataset represented in Figure 2 is used for the different link functions. The dots in this figure are the original observed \((X_i, Y_i)\)-pairs (or the rearranged \((X_i', Y_i')\)-pairs). The classical GLMs are represented by a plain line and the alternative GLMs by a dashed line. We notice that there is not much difference between the two models. However, in the tails of the curves the alternative model always has a lower probability of perforation at the same velocity in comparison to the classical models. This is to be expected since the alternative model only allows strictly positive velocities. Therefore, it should have a tighter tail at low velocities and a thicker tail at high velocities.

The maximum likelihood estimators for \( \beta_0 \) and \( \beta_1 \) (e.g., \( \hat{\beta}_0 \) and \( \hat{\beta}_1 \) respectively) of each model are presented in Table 4, as well as the mean squared error (MSE).

We notice that the value of \( \hat{\beta}_1 \) is strictly positive in both models. This implies that the curves are strictly increasing. We expected such a result because we know that for an increasing speed of the bullet the probability of perforation will also increase. Based upon these results, we can also conclude that a logit model performs the best (lowest MSE). However, these are the results for only one vest type. Therefore, we compare all techniques and all data sets (of the different vest types) in Section 8.

Based upon the estimated parameter values we determined \( V_p \) for the different models with the expressions formulated in Table 3. Table 5 gives the estimated
Figure 3: The GLM estimates for the perforation probability $f(v)$ as a function of velocity $v$ for different link functions. The straight line is the classical link function and the dashed line is the alternative link function. The dots are the input data records.

velocities at which 1% ($V_{01}$) and 50% ($V_{50}$) of the bullets perforate the vest. This table also presents a 95% confidence interval for $V_p$. This interval is generated with the bootstrap method (or resampling): randomly selecting $N$ observations from the data with replacement and obtaining estimates for $V_p$ for the resulting bootstrap sample. We repeated this procedure many times, calculating estimates for each bootstrap replication. This gives a distribution for the estimate of $V_p$.

</table>

Table 5: The estimated velocities including their 95% confidence intervals.

For $V_{01}$ we notice that the estimates from the classical models are smaller compared to those from the alternative models. This is not a surprise since we mentioned already that the curves for $f(v)$ show lower values in the tails for the alternative models in comparison to the classical models (see Figure 3). The confidence intervals in the alternative models are smaller than in the classical models. This is because of the same reasoning.

## 5 Non-Parametric Models

In the previous section we fitted a curve according to generalized linear models. Such a technique assumes something about the form of the curve. When we do not want to make such an assumption, we have to fit a curve entirely based upon the data. The only restriction we have is that the curve should be monotonic increasing (i.e. non-decreasing). Most of the time, the data does not have this property (see Figure 2). Therefore, smoothing has to take place. This can be done in two different ways: either smooth the data first and then find the curve or find a curve on the rough data with the use of smoothing. An example of the first approach is isotonic regression and for the second approach smoothing splines can be used. The third approach we mention in this section is the use of loss functions, which are based upon empirical distributions. All three applications are discussed in this section and
we end with numerical results on the three methods.

5.1 Smoothing Splines

Splines are piecewise polynomial functions that fit together (Eubank [9]). In particular, for cubic splines, the first and second derivatives are also continuous in every point. Smoothing splines are curves that get reasonably close to the data in a graceful manner such that it gives the appearance of a single curve.

Smoothing splines arise as the solution to the following simple-regression problem: Find the function \( \hat{f}(x) \) with two continuous derivatives that minimizes the penalised sum of squares,

\[
SS^*(h) = \sum_{i=1}^{n} [y_i - f(x_i)]^2 + h \int_{x_{\min}}^{x_{\max}} [f''(x)]^2 \, dx,
\]

where \( h \) is a smoothing parameter (Fox [11]). The first term in Equation (7) is the residual sum of squares. The second term is a roughness penalty, which is large when the integrated second derivative of the regression function \( f''(x) \) is large. The endpoints of the integral enclose the data. At one extreme, when the smoothing constant is set to \( h = 0 \) (and if all the \( x \)-values are distinct), \( \hat{f}(x) \) simply interpolates the data. So, small values of \( h \) correspond to more emphasis on goodness-of-fit. Conversely, when \( h \) is large it places a premium on smoothness. Typically \( h \in (0, 1] \).

Since we are interested in a monotonically increasing function, we set \( h \) to the smallest smoothing parameter such that this restriction is satisfied.

5.2 Isotonic Regression

Isotonic regression is a non-parametric method that is used when a dependent response variable is monotonically related to an independent predictor variable (Barlow et al. [3] and Robertson et al. [15]). We are indeed looking for an isotonic (i.e., non-decreasing) function where the probability of perforation \( f(v) \) depends on the velocity \( v \) of the bullet. A commonly used algorithm for computing the isotonic regression is the pair-adjacent violators algorithm (PAVA), which calculates the least squares isotonic regression of the data set (Barlow et al. [3] and Robertson et al. [15]).

The basic idea of PAVA is the following: sort the \((x_i, y_i)\)-data pairs such that \( x_1 \leq x_2 \leq \ldots \leq x_N \). If \( y_1 \leq y_2 \leq \ldots \leq y_N \), then all points are increasing and the algorithm stops. Otherwise, select the first data pair \( i \) for which \( y_i > y_{i+1} \). In that case replace \((x_i, y_i)\) and \((x_{i+1}, y_{i+1})\) by their weighted average \((x_i^*, y_i^*)\), where

\[
\begin{align*}
x_i^* &= \frac{w_i x_i + w_{i+1} x_{i+1}}{w_i + w_{i+1}}, \\
y_i^* &= \frac{w_i y_i + w_{i+1} y_{i+1}}{w_i + w_{i+1}}, \\
w_i^* &= w_i + w_{i+1}.
\end{align*}
\]

This procedure is repeated until the algorithm terminates. The algorithm starts with weights equal to one \( (w_i = 1 \text{ for } i = 1, 2, \ldots, N) \). The algorithm is applied upon the data of Teijin Twaron and represented in Figure 4.
Now the new data set is such that it is non-decreasing. We can easily find an interpolation scheme to connect the data points and find \( f(v) \). We make use of two interpolation schemes in Section 5.4: stepwise interpolation and piecewise linear interpolation.

![Figure 4: We transformed the data from rough data (dots) to monotone increased data (triangle).](image)

5.3 Loss Function

In this section we describe a method that determines the probability of perforation (or the function \( f(v) \)) entirely based on empirical distributions. Besides this function \( f(v) \), this approach also requires a probability density function of the velocity \( v \), denoted by \( g(v) \). Based on the data we can consider the empirical density function of the velocity (denoted by \( G \)) and the empirical distribution of \( f(v) \) (denoted by \( F \)). So,

\[
F(x_i) = \begin{cases} 
1, & \text{if } y_i = 1, \\
0, & \text{otherwise.}
\end{cases}
\]
We want to minimize the result to obtain an estimator for $f^{-1}(p)$. This function is called a loss function. Select positive $\alpha$ and $\beta$ and define the loss function as

$$L(a) = \alpha \int_0^a f(v)g(v)dv + \beta \int_a^\infty (1 - f(v))g(v)dv.$$ 

To minimize $L$, we take the derivative to $a$ and set it equal to 0:

$$\frac{\partial}{\partial a} L(a) = (\alpha f(a) - \beta (1 - f(a))) g(a) = 0, \quad (8)$$

Equation (8) is solved by $a^*$ with

$$f(a^*) = \frac{\beta}{\alpha + \beta}.$$ 

Note that

$$\frac{\partial^2 L(a)}{\partial a^2} = (\alpha + \beta) g(a) \frac{\partial}{\partial a} f(a) + (\alpha f(a) - \beta (1 - f(a))) \frac{\partial}{\partial a} g(a),$$

such that

$$\frac{\partial^2 L(a)}{\partial a^2} \bigg|_{a=a^*} = (\alpha + \beta) \frac{\partial}{\partial a} f(a) \bigg|_{a=a^*} g(a^*) \geq 0$$

because $f(v)$ is increasing in $v$ and $\alpha f(a^*) - \beta (1 - f(a^*)) = 0$, using Equation (8). It means that $a^*$ is the minimizer of $L$. We may set $p = \beta/(\beta + \alpha)$. For simplicity, we take $\beta = 1$ and $\alpha = 1/p - 1$. To estimate the inverse of $f(v)$ (i.e., $f^{-1}(p)$), it is now enough to minimize the empirical counterpart of $L$, namely

$$L(\alpha) = \left( \frac{1}{p} - 1 \right) \int_0^a f(x)g(x)dx + \beta \int_a^\infty (1 - f(x))g(x)dx$$

$$= \left( \frac{1}{p} - 1 \right) \sum_{i=1}^n 1_{x_i < a, y_i = 1} + 1_{x_i \geq a, y_i = 0}.$$ 

We select $m \in \mathbb{N}$ and for $j = 1, \ldots, m$, we set $p = 1/j$ and minimize $L$ to obtain $\hat{f}^{-1}(1/j)$.

5.4 Numerical Results

All three non-parametric approaches are implemented and the resulting functions $f(v)$ for each approach are presented in Figure 5. The inverses of these functions yield the estimator for $V_p$. With the use of resampling we constructed a 95% confidence interval (see also Section 4.4). The results are represented in Table 6. This table also represents the MSE for each technique.

6 Bootstrap Method

In the previous two sections we were interested in finding a function $f(v)$ in order to determine $V_p$. In this section we rewrite $f(v)$ as a conditional probability

$$f(v) = P(Y = 1|X = v),$$
Figure 5: The estimates for the perforation probability $f(v)$ as a function of velocity $v$ for different non-parametric approaches. The dots are the input data records.

Table 6: The estimated velocities including their 95% confidence intervals.

the probability of perforation under the condition that the velocity $X$ equals $v$. Now,

$$P(Y = 1|X = V_p) = p \quad \quad P(Y = 0|X = V_p) = 1 - p. \quad (9)$$
Using Bayes rule, we can rewrite Equation (9) as

\[
P(Y = 1|X = V_p) = \frac{P(X = V_p|Y = 1)P(Y = 1)}{P(X = V_p)},
\]

(10)

and

\[
P(Y = 0|X = V_p) = \frac{P(X = V_p|Y = 0)P(Y = 0)}{P(X = V_p)}.
\]

(11)

Dividing Equation (10) by Equation (11) and use Equation (9), we get the following expression

\[
\frac{p}{1 - p} = \frac{P(X = V_p|Y = 1)P(Y = 1)}{P(X = V_p|Y = 0) (1 - P(Y = 1))}.
\]

(12)

Now we have to compute each of the components of Equation (12). Let us first look at \(P(Y = 1)\), i.e. the proportion of data records of which the bullet perforates the vest. This can be estimated directly from the data. The two other probabilities can also be derived directly from the data for every observed velocity \(x_i, i = 1, \ldots, N\), where

1. \(P(X = x_i|Y = 1)\) is the frequency at which we observe velocity \(x_i\) when the vest is perforated, and
2. \(P(X = x_i|Y = 0)\) is the frequency at which we observe velocity \(x_i\) when the vest is not perforated.

Since the property of Equation (12) holds for \(V_p\) we calculate the ratio

\[
\frac{P(X = x_i|Y = 1)P(Y = 1)}{P(X = x_i|Y = 0) (1 - P(Y = 1))},
\]

for each observed velocity \(x_i\) and the one that is closest to \(p/(1 - p)\) is the estimate for \(V_p\).

The main problems with this approach are the few data points in each conditional distribution of the velocity and the fact that we can find different velocities that are closest to the property of \(V_p\). To overcome the first problem we propose to use the bootstrap method to get a distribution for \(V_p\), which allows us to estimate \(V_p\) with the average and to construct a 95% confidence interval. The second problem (of multiple velocities satisfying Equation (12)) is solved for \(V_{50}\) by taking the median and for \(V_{01}\) the minimum value of those velocities is selected.

### 6.1 Verification

In order to verify whether the algorithm performs well, we can generate samples from known distributions (like normal or weibull) that can be used as input. For known distributions, we know what the outcome of the algorithm should be. With the use of a small Monte-Carlo simulation experiment we can test the performance. Table 7 shows the deviation of the result from algorithm with the true outcome for different distributions. The parameters for the distributions are such that the mean and variance are equal as the data set of Teijin Twaron. Based on these results, we can conclude that the algorithm works well for most distributions.
distribution & percentage deviation
\hline
chi-square & 5.35\% & 6.30\% \\
gamma & 5.51\% & 6.30\% \\
logistic & 5.21\% & 9.17\% \\
log-normal & 72.1\% & 3616.41\% \\
normal & 5.34\% & 6.89\% \\
stUDENT & 0.33\% & 1.07\% \\
uniform & 5.78\% & 1.90\% \\
\hline
\end{tabular}

Table 7: To verify the bootstrap method, we performed the method with known distributions and therefore the actual outcome is known as well.

6.2 Numerical Results

When we apply the proposed procedure to the dataset, the resulting estimates for both $V_{50}$ and $V_{01}$ are presented in Table 8 including the 95\% confidence intervals. Based on these results we conclude that the estimates for $V_{50}$ have a large 95\% confidence interval and for $V_{01}$ a rather small interval. This is because the data is collected in a way to determine $V_{50}$. As a result, not much different velocities are detected satisfying the property as defined in Equation (12) for $V_{01}$.

7 Experimental Set-Up

The current design of the experiment set-up was originally developed to determine $V_{50}$ (see Section 1). With the same data Teijin Twaron wants to make statements about $V_p$ for arbitrary $p$. Also in other fields where quantile estimation plays an important role we see a shift towards generalization. In this section we give some recommendations on the design of future experiments.
The median ($p = 50\%$) is the most commonly used measure of characteristic of the response curve. In some situations this estimation is of intrinsic interest, but more often it is because this quantile is the easiest to estimate (Wu [18]). Recently, several designs have been proposed for estimating quantiles where $10\% \leq p \leq 90\%$ (Wu [18], Stylianou and Flournoy [17]). The designs that are typically suggested are so-called adaptive or sequential designs where the velocity for a run is based on the response (perforation or no perforation) in the previous run(s). So in the current design used by Teijin Twaron is also adaptive (see Section 1). Except in the extreme tails of the quantile response function, the optimal design for estimating a particular quantile is a one-point design at the (unknown) target quantile (Ford et al. [10]). Hence, a good adaptive strategy should result in taking relatively much observations around the velocity $V_p$ of interest. An adaptive strategy, that has been shown to work fine for values of $p$ between 10\% and 50\% is discussed in section 7.1. We end this section with addressing the problems that arise when this probability of interest is small.

7.1 Adaptive Designs

Stylianou and Flournoy [17] proposed an adaptive design called the up-and-down Biased Coin Design (BCD). Giovagnoli and Pintacuda [12] showed that the BCD is optimal within a large class of generalised up-and-down biased coin designs in the sense that the distribution of the velocities considered in the experiment is most peaked around $V_p$.

Before the BCD procedure starts performing the experiments, a collection of velocities of interest $\Omega = \{v_1 < v_2 < \ldots < v_K\}$ is set. The target velocity $V_p$ should be in the range of $\Omega$. In the first experiment a bullet is shot at velocity $v \in \Omega$. The velocity $v$ may be fixed (e.g. the velocity that is thought to be closest to the target value $V_p$) or random. If the bullet perforated the vest, the next velocity to shoot with is one slower from $\Omega$. However if the bullet did not perforate the vest, the procedure randomizes: Since we only consider cases where $p \leq 50\%$, the velocity becomes higher according to $\Omega$ with probability $p/(1 - p)$ and with probability $(1-2p)/(1-p)$ the same velocity is used in the next shot. Appropriate adjustments need to be made at the lowest and highest velocities in $\Omega$.

7.2 Small perforation probabilities

Not much is known about the design of experiments when the percentage $p$ is smaller than 10\%. A major problem is that the response is binary, which means that the amount of information that we gather each run is very small. Most of the bullets fired at velocities around $V_p$ will be stopped for small values of $p$. However, some perforations for velocities around $V_p$ are needed in order to estimate the probability of perforation at these velocities and eventually to help locating velocity $V_p$. Let us denote $N_p^r$ as the number of shotes fired at the vest with velocity $V_p$ until the $r$-th perforation occurs. Under the assumption that bullets are fired independently, this random variable has a negative binomial distribution with parameters $p$ and $r$. The
The probability distribution function is given by Equation (13).

\[ P(N^r_p = n) = \binom{n - 1}{r - 1} p^r (1 - p)^{n-r}, \quad n \geq r. \]  

(13)

The expectation and the variance of \( N^r_p \) equals

\[ E[N^r_p] = \frac{r}{p}, \quad Var[N^r_p] = \frac{r(1 - p)}{p}. \]

Table 9 gives some details of the distribution of \( N^r_p \) for some small perforation probabilities \( p \) and different values of \( r \). When the number of experiments is limited to 150 (or even 500) it will be difficult to locate the velocities \( V_p \) for small values of \( p \) using only the binary response. Using the depth of the perforation (e.g. the number of perforated layers) as a response variable may be a better way to gather more information from a single shot and to reduce the total number of shots required to determine \( V_p \) for small values of \( p \).

8 Conclusions

In this paper we investigated the factors that influence the probability that a bullet perforates a bullet proof vest. Section 2 made clear that the velocity of the bullet and how many times you shoot at the vest are most important. This is something new for Teijin Twaron, since they assumed independence between the different shots with the shooting pattern they use. Therefore, we recommend to look into this phenomenon and investigate their shooting pattern. The data analysis also showed that the vest type is of less importance. This is a bit strange, since Teijin Twaron wants to compare different vest types by their perforation probabilities. It is, however, very well possible that the influence of the other aspects suppress the influence of the vest type.

8.1 Comparing Techniques to Estimate \( V_p \)

In the remainder of the paper we investigated the relationship between the velocity \( v \) and the probability of perforation for every vest type. In particular we have
developed several procedures to determine the velocity at which \( p \) percent of the bullets go through the vest (denoted by \( V_p \)). In the different methods a function \( f(v) \) is established which describes this relationship.

When we would like to compare the different approaches that are proposed in this paper, we use the mean squared error as measure of fitness (see Section ??). This measure can be computed for all data sets corresponding with different vest types. In total there are ten data sets. Table 10 shows the performance of the current model on all samples.

to perform better around the data points. Therefore, we recommend Teijin Twaron to use loss functions. But also the logistics model (logit model) and the isotonic regression approach with linear interpolation perform well. Especially when the confidence interval is of interest, we recommend the latter two techniques.

The final technique we developed is a bootstrap method in which a particular characteristic at $V_p$ is determined based upon conditional probabilities. A disadvantage of this procedure is that it will only work nicely for particular values of $p$ ($p = 1\%$ and $p = 50\%$ work fine). This procedure will probably give the same results for $p = 1\%$ and $p = 10\%$. This is not likely to happen in reality.

### 8.2 Experimental Design

Besides the technique to determine $V_p$, Teijin Twaron also has to change their set-up of the experiments (the shootings at the vest). Their design is currently developed.
to determine $V_{50}$. When they want to determine $V_{01}$ (or any other $V_p$ for a particular value of $p$) they need different data records. The data records to determine $V_p$ should concentrate on the influence of the velocity on the perforation probability around $V_p$. Therefore, we propose a Biased Coin Design, that has been proven to work well in practice for values of $p$ between 10% and 50%. If, however, Teijin Twaron wants to estimate $V_{01}$, they will not find a good predictor with this design where they only look at perforation of the vest of no perforation. They need to use other information as well, like the number of perforated layers. Otherwise, the number of experiment to perform becomes more than thousand.
